## **Introduction**

This technical memorandum presents the results of activities conducted to evaluate groundwater quality within M-Series wells at the Dundalk Marine Terminal (DMT) located in Baltimore, MD. These activities were performed between November 2006 and March 2007 to address Maryland Department of the Environment's (MDE) inquiry concerning groundwater quality within the Lower Patapsco Aquifer. A scope of work was developed to evaluate the groundwater quality which included collection of groundwater from existing intermediate wells using conventional purging and sampling techniques and then comparing these results with data from colocated shallow monitoring wells. The scope also included sampling of soils within the Alluvial and Lower Patapsco sediments for chemical and geotechnical analyses during the installation of five intermediate wells during Phase 1 of the COPR Investigation. The following sections contain a brief description of the scope completed, a summary of the resulting data, and the results of the assessment. The assessment results were previously submitted to MDE on June 12, 2007.

As explained below, multiple lines of evidence indicate that there is no significant vertical migration of COPR-impacted groundwater into the Lower Patapsco Aquifer beneath the DMT. Although low levels of hexavalent chromium were detected in a few highly localized soil samples, these samples are not believed to be representative but are likely caused by cross contamination attributable to the drilling and sampling methods used. Groundwater monitoring wells were installed at each boring with a corresponding soil detection and will serve as long-term monitoring points.

## **Conventional Purging and Sampling of Existing Monitoring Wells**

CH2M HILL performed conventional purging and sampling at monitoring wells EAC-1M, EAC-4M, EA-5M, EA-6M, EA-11M, EA-13M, and EA-15M to monitor geochemical parameters and chromium concentrations at initiation, during, and at completion of well purging. MDE had observed that samples collected from monitoring wells EAC-1M, EAC-

4M, EA-6M, EA-13M, and EA-15M have either had elevated pH values or exhibited increasing pH trends. Monitoring wells EA-5M and EA-11M did not exhibit historically elevated pH values, but served as control wells in this assessment. In addition, a sample was collected from shallow monitoring wells colocated with each of these M-Series wells (EAC-1S, EAC-4S, DMT-25S, EA-6S, EA-11S, P-4, and EA-15S) using low-flow purging and sampling techniques to compare geochemical characteristics with the EA M-Series wells. These wells are shown on Figure 1.

Groundwater samples were collected at the beginning and end of purging of the M-Series wells for chemical analyses. In addition, field parameters including temperature, specific conductance, dissolved oxygen, pH, oxidation reduction potential (ORP), turbidity, and salinity were collected at regular intervals during purging. An attempt was made to purge at least 3 to 5 well volumes from each of the EA M-Series wells to ensure that the collected groundwater was representative of the formation. Efforts were successful in removing a minimum of three well volumes in all of the EA M-Series wells except for EA-5M and EA-11M. Pumping could not be sustained in either of these wells at pumping rates ranging from approximately 1 to 5 gallons a minute and each of these wells went dry. As a result, samples were collected from these wells using lower flow rates that minimized drawdown. A minimum of one well volume was removed from each of these wells prior to sampling.

One sample was collected from each of the colocated shallow monitoring wells using low-flow purging and sampling techniques. Each of the groundwater samples collected for laboratory analyses were handled in accordance with CH2M HILL's 2006 draft "COPR Investigation Work Plan," and laboratory analyses were performed by Accutest Laboratories of Dayton, NJ.

## Results of field Parameter Measurements

The field parameter measurements and graphs showing pH values during the well purging process are included in Attachment 1. The following observations have been made from the field parameter measurements:

- Shallow groundwater collected from within areas of known COPR, or located hydraulically downgradient of areas of known COPR (EAC-4S, DMT-25S, EA-6S, P-4, and EA-15S), show pH values greater than 12.0 and lower ORP values than wells located outside of COPR (EAC-1S and EA-11S) where pH values were in the neutral range.
- Each EA M-Series well showed initial pH values higher than those values after purging was completed.
- Each EA M-Series wells exhibiting elevated pH showed a marked decrease in pH during the initial stages of purging and pH values that were generally in the neutral range at the end of the purging with the exception of EAC-4M, which declined from a pH of 9 to a pH of 8.
- Monitoring wells EAC-1M and EAC-5M showed a multiple-unit decrease between the initial reading at commencement of pumping and at completion of purging, but the remaining of the wells showed a decrease in pH of less than one unit.

The initial drop in pH values in the M-Series wells is thought to be the result of the purging of “stagnant” water within the well casing and the stabilization of pH values is considered representative of formation water entering the well screen.

Monitoring well EAC-4M is the only well in which pH values did not stabilize below 8.0; however, pH values did stabilize at 8.03. Well EAC-4M is located outside of the COPR boundary and is screened from approximately 40 to 50 feet below ground surface, which would suggest that EAC-4M is screened within the lower yielding Alluvial Sediments, believed to function as a confining unit at the site. EAC-4M is not considered representative of water quality within the Lower Patapsco, which is the aquifer of concern. Furthermore, a tidal influence evaluation performed on this well for the Chromium Transport Study showed that this well has little to no tidal influence.

## Results of Chromium Analyses

The analytical results for the groundwater samples collected from the shallow wells and from the M-Series wells at the initiation and conclusion of purging are included as Attachment 2. The following observations have been made from the total chromium and hexavalent chromium analytical results:

- Elevated total chromium values (above the 100 ug/L Federal Drinking Water Maximum Contaminant Level [MCL]) were detected in filtered and unfiltered samples from each of the shallow groundwater wells installed within or immediately downgradient of known COPR placement.
- Hexavalent chromium was detected in each of the filtered and unfiltered samples from each shallow groundwater wells installed within or downgradient of known COPR placement.
- Total chromium was detected in M-Series wells below the MCL in all samples collected except the initial unfiltered sample collected from well EA-13M. The corresponding filtered sample contained total chromium concentrations well below the MCL.
- At the conclusion of purging EA-13M, total chromium was again detected well below the MCL in the unfiltered sample.
- Hexavalent chromium was detected in the sample collected at the initiation of purging in EA-13M, but was not detected in the corresponding filtered sample or from either the unfiltered or filtered sample at the conclusion of purging.
- Hexavalent chromium was detected at low levels in the unfiltered samples collected at the beginning and conclusion of purging M-Series well EAC-4M at estimated concentrations well below the laboratory reporting limit, but hexavalent chromium was not detected in either filtered samples collected at EAC-4M.

The detection of hexavalent chromium in the initial sample from EA-13M is believed to be the result of turbidity at the initiation of purging and suggests that solids containing hexavalent chromium were present in the well screen. It is not suspected that these solids would enter the well through the well screen from the formation as the well is screened well below any fill material containing COPR. It is more likely that solids would enter the well

either from a damaged well casing or from debris at the surface. Particular attention should be given to future data from EA-13M.

## Comparison of Geochemical Data

Groundwater samples were collected from the shallow and M-Series wells for laboratory analyses of geochemical parameters. Attachment 3 contains trilinear diagrams showing the major ion percentages in groundwater for each of the well pairs. Attachment 3 also contains a table summarizing the relative percentage of major ions contained in each of the groundwater samples. The following observations have been made from the geochemical results:

- The trilinear plots clearly illustrate that the geochemical “signature” of the groundwater samples collected at the initiation of purging the M-Series wells is the same as groundwater samples collected at the conclusion of purging, with the exception of the groundwater samples collected at EA-5M. Groundwater could not be purged from EA-5M at a sustained rate, and it is believed that the initial sample collected from EA-5M represents “stagnant” water within the well casing at the initiation of purging, due to limited flow to and through the well.
- Trilinear plots for groundwater samples collected from the colocated shallow wells contain significantly different percentages of major ions than groundwater samples collected from the M-Series wells.
  - The percentage of calcium in shallow groundwater is generally 1½ to 4 times greater than the percentage of calcium in the deep zone.
  - Shallow groundwater, particularly in areas of known COPR, or located hydraulically downgradient of areas of known COPR, contained little to no magnesium, while magnesium generally comprised almost 20 percent of the ionic composition of the deep zone.
  - The anion composition of the deep zone groundwater is dominated by chloride and sulfate, whereas the shallow groundwater composition is dominated by bicarbonate.
- At each colocated well pair, and in general across the site, the carbon dioxide concentration in the deep zone is generally one to two orders of magnitude greater than observed in the shallow groundwater indicating that a fairly significant barrier exists between the two zones, limiting the transfer of carbon dioxide.

The difference in cation and anion composition between the shallow groundwater and deep zone groundwater at the site suggests that there is no connection between shallow groundwater and the M-Series wells at DMT. Furthermore, the large difference in carbon dioxide composition between the two zones suggests that a significant barrier to groundwater flow exists between the two zones.

## Results of Soil Analyses

In addition to the collection of groundwater samples from existing wells at DMT, CH2M HILL collected soil samples at various depths through the shallow and deep soils during the installation of five new monitoring wells (DMT-34M through DMT-38M) completed in the

Lower Patapsco sand and gravel unit beneath the site. The results of the soil samples are included as Attachment 4.

Several soil samples collected at depths below the alluvial silts and clays contained low concentration detections of hexavalent chromium (Cr (VI)) and/or elevated pH values (defined as >8.5). The concentrations of Cr(VI) detected below COPR and the confining silts and clays are below the USEPA Region 3 soil to groundwater soil screening level (SSL) of 42 mg/kg. The analytical soil data has been evaluated to identify trends or geochemical evidence to determine whether shallow COPR may be impacting soil and groundwater in the Patapsco Formation. Particular attention was paid to the geochemistry, the lithology and the groundwater quality from the associated wells to determine the validity of the detections. Total chromium was not detected at elevated concentrations below COPR and was not evaluated during this process. The following section presents a summary of the evaluation.

Several lines of evidence exist that suggest that both the elevated pH values and low concentration detections of Cr(VI) are anomalous and are not indicative of actual soil conditions:

- Soil sample results from each of the boreholes where COPR was encountered show a significant decrease of pH, total Cr and Cr(VI) immediately below the COPR. Total Cr and Cr(VI) concentrations decrease between one and four orders of magnitude immediately below COPR. The pH values also decrease generally three to four standard units immediately below the COPR. If downward migration of Cr(VI) and high pH groundwater were occurring from the overlying COPR, a more linear trend in soil concentrations would be expected.
- Any downward migration of Cr(VI) in groundwater would pass through the organic rich soils that immediately underlie COPR at the site. These soils drive reduction of Cr(VI). Cr(VI) in groundwater would be reduced to Cr(III), which is relatively immobile at the neutral pH values observed below COPR. This is further demonstrated by the significant decrease in Cr(VI) detections immediately below COPR.
- Unlike the relatively immobile Cr(III), Cr(VI) is soluble and Cr(VI) migrating downward would be detectable in groundwater due to its solubility. Cr(VI) is not routinely detected in groundwater from any of these M-series wells when representative formation waters are sampled and analyzed.
- All detections of Cr(VI) in soils at depth are below or immediately above the laboratory reporting limit. Several different and sample specific laboratory inaccuracies, such as a large variation in laboratory replicates, have been identified for these samples which could indicate that some low level detections were false positive results.
- Several (4) elevated soil pH values were recorded at depth in several of the boreholes. In each borehole where this occurred, multiple soil samples were collected at a shallower depth (between COPR and the sample in question) that showed neutral values. It is unlikely for COPR impacted groundwater to pass through or around each of these zones where neutral soils were observed and impose elevated pH values on soil at depth.

- Soils showing elevated pH values at depth were two to four standard units greater than soil samples collected immediately above and below that were generally collected from the same lithologic unit.
- Groundwater collected from the completed monitoring wells show neutral pH values which are several standard units below the soil samples with elevated pH. The monitoring wells are generally screened within the same lithology as the soil samples in question. The elevated pH values detected in the soils in question cannot exist at several standard units greater than the groundwater in the soil pore spaces and not impact groundwater chemistry.
- Several of the soil samples showing elevated pH were collected from zones of coarse grained material. The soils of the Patapsco Formation are derived from crystalline (igneous and metamorphic) rock and were deposited in a non-marine environment. Thus the mineralogy of the Patapsco Formation does not contain sufficient calcium and magnesium to elevate pH in the surrounding groundwater.

Several potential causes of the anomalous elevated pH values and low level Cr(VI) detections have been identified:

- Each monitoring well was installed with a six-inch diameter steel permanent outer casing that was set in the silt and clay material beneath fill and grouted in place. This steel casing is designed to separate the COPR material in the fill zone from deeper soils in the borehole. There is the potential that an incompletely sealed casing could allow for migration of Cr(VI) by water containing these constituents into the borehole and downward during advancement of the borehole.
- The wells were installed using mud rotary drilling techniques. This technique uses a bentonite slurry ( $\text{pH} > 9$ ) that is continuously circulated within the borehole to keep the borehole walls from collapsing during advancement of the borehole. Because soil sampling during the installation of the borehole is accomplished using standard penetration testing through the drilling mud, a layer of drilling mud typically coats the outside of the soil core sample that is submitted to the lab for analysis.
- Despite efforts to decontaminate rotary mud pumps, hoses and equipment, and to limit contaminated mud from entering the annulus after the protective casing has been set, there is always the possibility that small levels of hexavalent chromium may be present as a cross-contaminant in the drilling mud. Any Cr(VI) introduced into the drilling mud would then be circulated with the drilling mud over the length of the borehole. Coarse grained, positive ORP material from the Patapsco formation would have little pH buffering capacity or hexavalent chromium reducing capacity resulting from the intrusion of drilling mud into the sample.
- Inherent and large variation in laboratory replications suggesting that some of the low level detections of Cr(VI) are indistinguishable from a non-detect result.

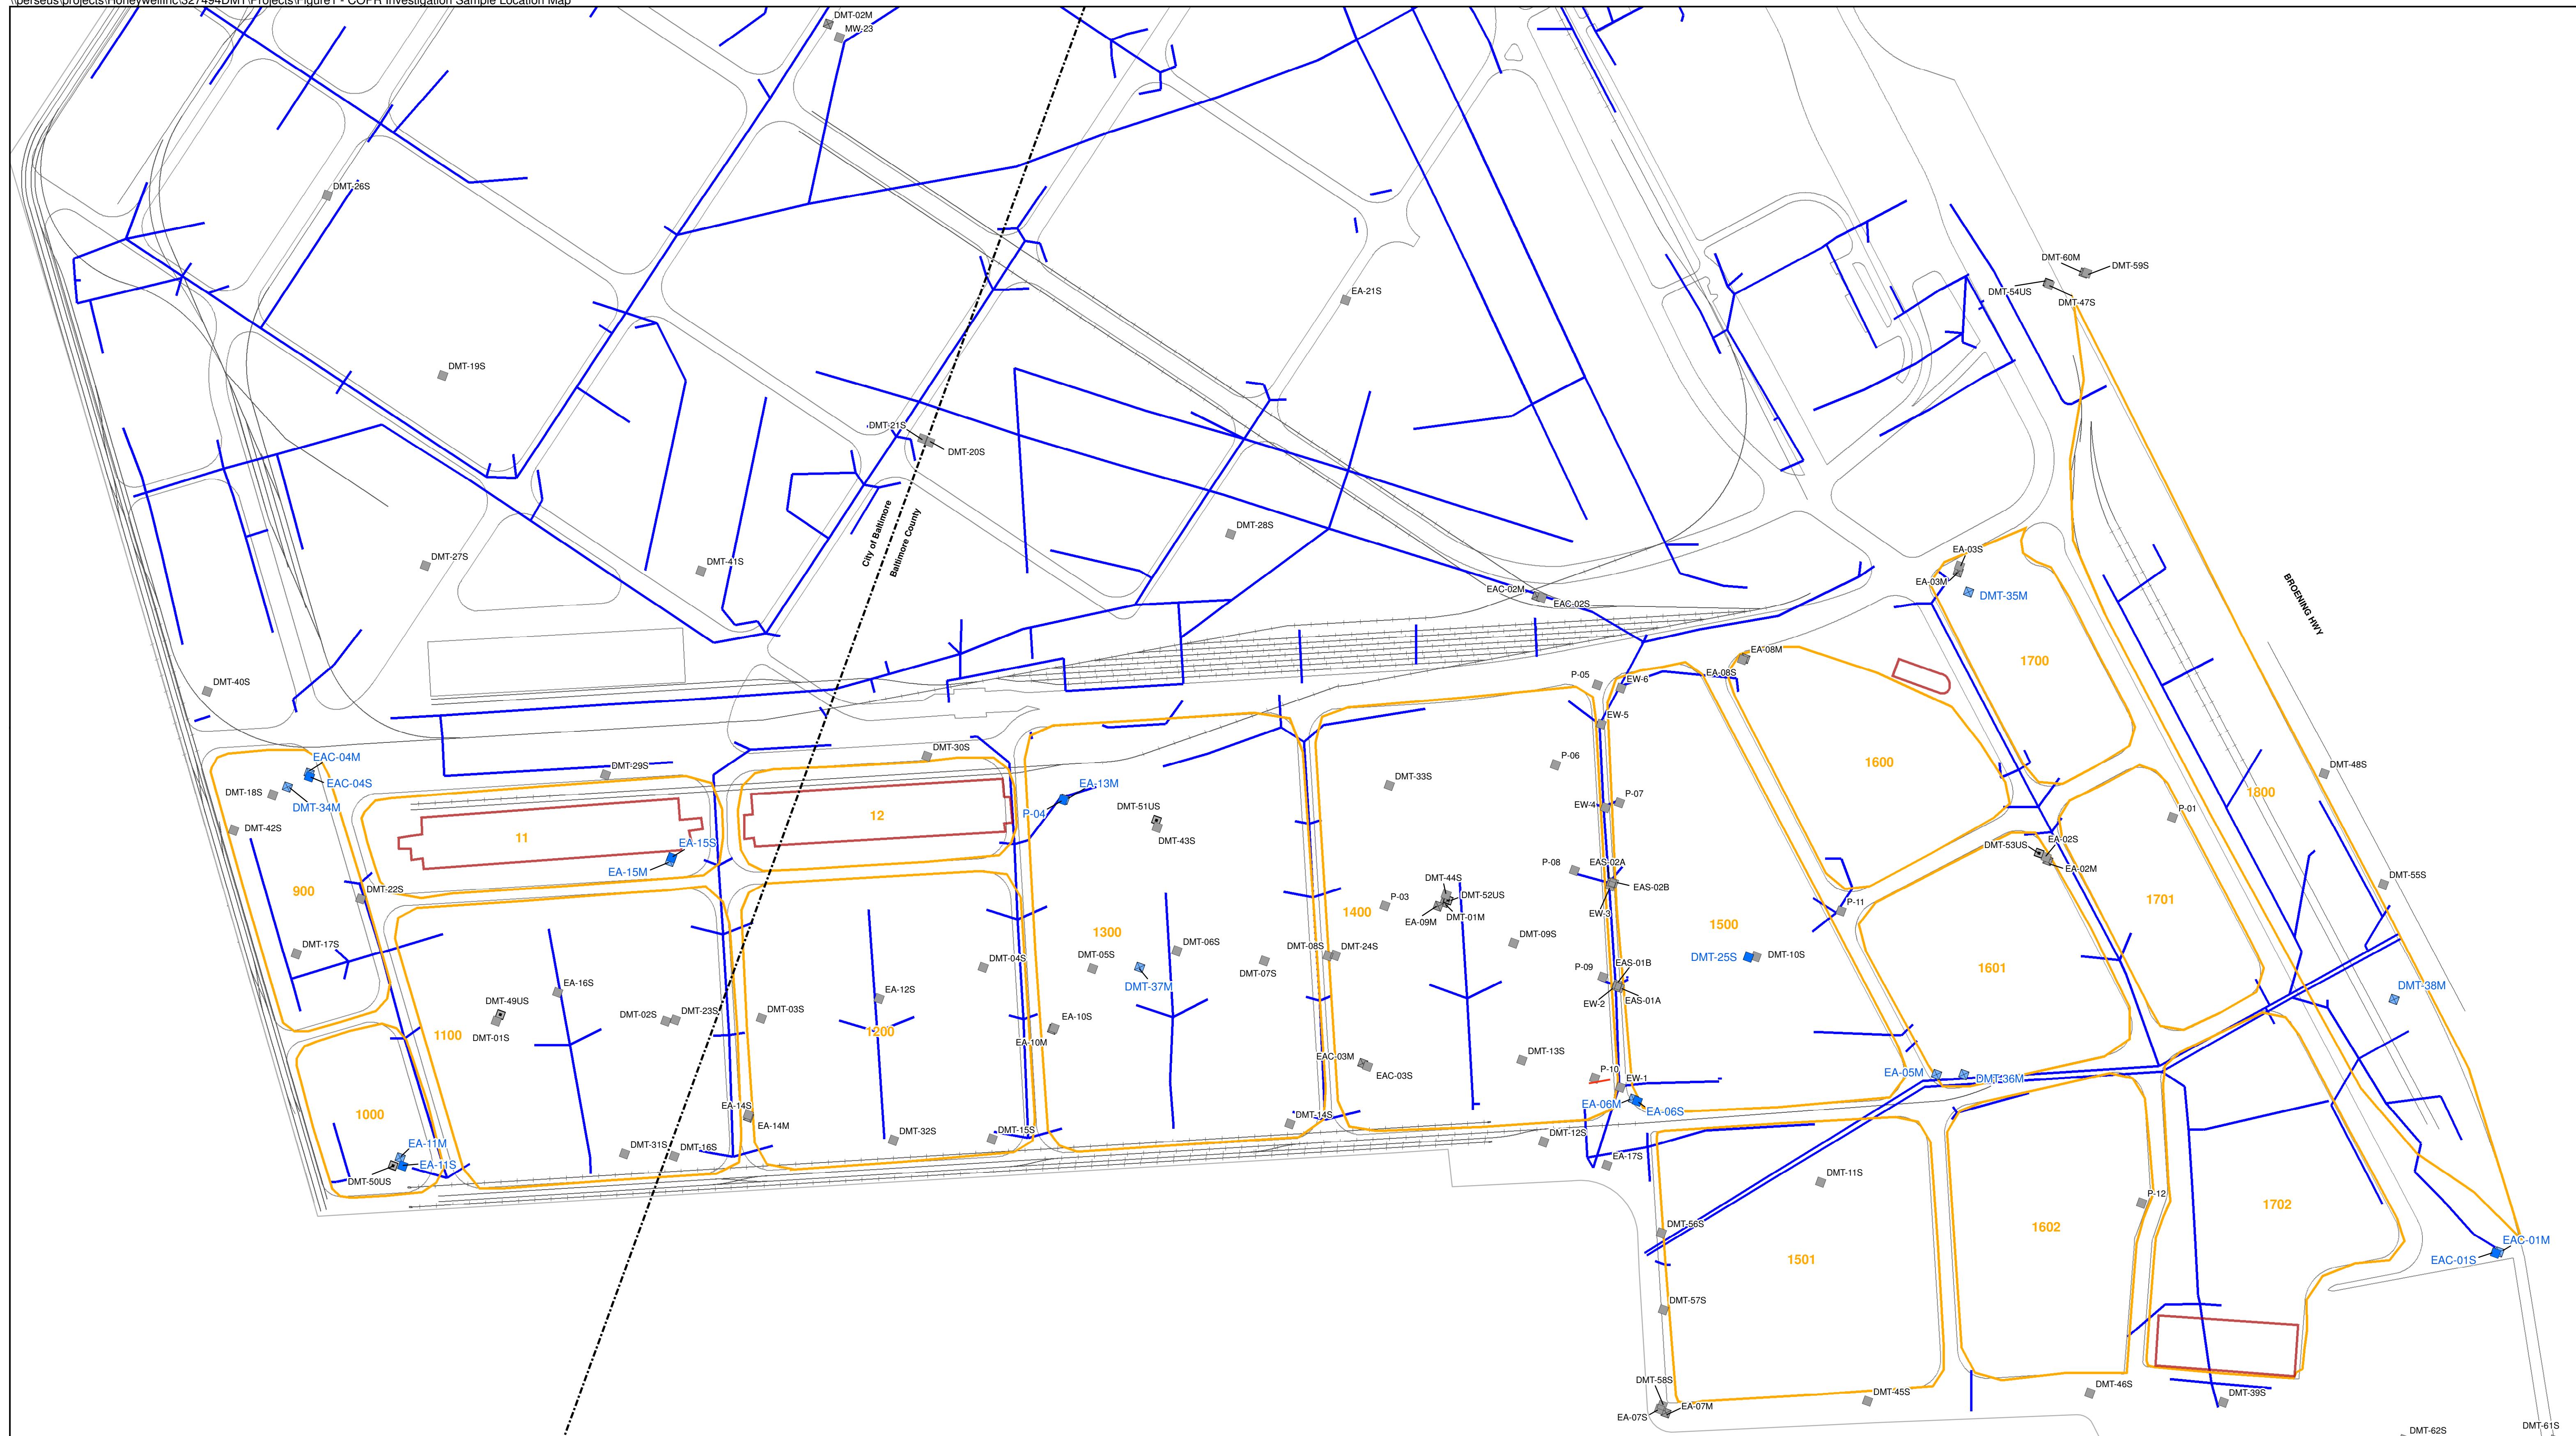

## Conclusions

Field recorded pH values in the M-Series monitoring wells suggest that some degree of "stagnation" exists within the well screen prior to significant purging of water within the well. The source of this stagnation is not fully understood but it could be caused by small leakage in well seals or casings. Such small leakage does not necessarily mean that the older monitoring wells are not useful, but rather sampling of these wells should be accomplished using traditional 3 to 5 volume purging techniques.

The following lines of evidence support the conclusion that shallow groundwater is having no meaningful impact on the M-Series wells at DMT:

- pH values were observed in M-Series wells that have historically shown elevated pH during a process of purging multiple well volumes from each well; generally, neutral pH values were recorded in each of these wells at the conclusion of pumping.
- Total chromium values below the Federal drinking water standard were recorded at the end of purging for each of the M-Series wells
- Major cation and anion composition of groundwater collected from shallow and M-Series wells across the site differ significantly suggesting the confining unit is effectively separating the fill unit and Patapsco aquifers.
- A one- to two-orders-of-magnitude difference in carbon dioxide concentrations between the shallow and deep zones supports the existence of a significant barrier between these lithologic zones.
- Low level detections of hexavalent chromium, at or near the analytical detection limit and well below the USEPA Region 3 soil to groundwater soil screening level (SSL) of 42 mg/kg., and slightly elevated pH have been detected in some soil samples during the installation of five new Lower Patapsco wells. The samples showing elevated pH values and containing low level Cr(VI) are believed to be anomalous based upon the lines of evidence presented above, and most likely have resulted from cross contamination due to the drilling and sampling methods employed. Monitoring wells have been installed in each of these boreholes and will be sampled as part of the long-term monitoring plan being developed for the site.

The results of these analyses suggest that no further action outside of routine groundwater monitoring is needed at this time to evaluate potential impacts of shallow, COPR affected groundwater on the Lower Patapsco Aquifer beneath the site. Conventional three-volume purging should be considered for future groundwater sampling events of the M-Series wells to document that a sample representative of formation water is obtained. While it appears that highly localized incidents of cross contamination have been identified for soil results as a consequence of the investigative methods employed, the concentrations are well below regulatory guidance and there appears to be no significant vertical migration of COPR impacted groundwater into the Lower Patapsco. Honeywell and MPA will be developing the Long-term Monitoring Plan for the site in accordance with the Consent Decree. The Plan will include an initial evaluation of monitoring wells that should be retained or decommissioned. In addition, the Plan will include a process for continued evaluation of the integrity and usefulness of monitoring wells within the program.
